Piperacillin concentration in relation to therapeutic range in critically ill patients – a prospective observational study

Johannes Zander¹, Gundula Döbbeler², Dorothea Nagel¹, Barbara Maier¹, Christina Scharf², Mikayil Huseyn-Zada¹, Jette Jung³, Lorenz Frey², Michael Vogeser¹ and Michael Zoller^{2*}

Abstract

Background: Piperacillin levels after standard dosing have been shown frequently to be subtherapeutic, especially when renal clearance was augmented. Here, we aimed to determine if piperacillin was in its therapeutic range in a typically heterogeneous intensive care unit patient group, and also to describe target attainment dependent on daily dosage, creatinine clearance, and renal replacement therapy (RRT).

Methods: Sixty patients with severe infections were included in this monocentric prospective observational study. Patients received 4.5 g of piperacillin-tazobactam two to three times daily by intermittent infusion depending on renal function according to clinical guidelines. Over 4 days, multiple serum samples (median per patient, 29; in total, 1627) were obtained to determine total piperacillin concentrations using ultra-high-performance liquid chromatography/tandem mass spectrometry.

Results: A high heterogeneity of patient characteristics was observed (e.g., on day 1: creatinine clearance 2–233 mL/min and ten patients on RRT). Piperacillin trough levels showed inter-individual variation from 123 to >1785-fold on different study days. Each day, approximately 50 % and 60 % of the patients had piperacillin levels below the target ranges 1 and 2, respectively [defined for the calculated unbound piperacillin fraction according to the literature as 100 % time above MIC (100 %fT > MIC) (target range 1) and ≥ 50 %fT > $4 \times$ MIC (target range 2); MIC = 16 mg/L]. Whereas only the minority of patients who received piperacillin-tazobactam three times daily (TID) reached target 1 (38 % on day 1), most patients who received piperacillin-tazobactam only twice daily (BID) because of severely impaired renal function reached this target (100 % on day 1). Patients with RRT had significant higher percentages of fT > MIC. Zero percent, 55 % and 100 % of patients without RRT who received antibiotics TID reached target 1 when creatinine clearance was > 65 mL/min, 30–65 mL/min and < 30 mL/min, respectively. In patients with causative strains only sensitive to piperacillin-tazobactam of all antibiotics given to the patient, piperacillin levels negatively correlated with CRP concentrations of day 4 ($p < 0.05$).

Conclusions: A dosage of 4.5 g piperacillin-tazobactam TID seems to be frequently insufficient in critically ill patients, and also in patients where renal function is mildly to moderately impaired. For these patients, prescription of 4.5 g piperacillin-tazobactam four times daily could be considered.

Trial registration: Clinicaltrials.gov NCT01793012. Registered 24 January 2013.

Background

Severe infections are a leading cause of the observed high morbidity and mortality in intensive care unit (ICU) patients. A key element for optimal patient outcomes includes sufficiently high antimicrobial concentration levels [1]. Such concentrations are also important for preventing the development of antimicrobial resistance [2, 3].

Piperacillin (PIP) is one of the most commonly used antibiotics in ICUs [4, 5]. This hydrophilic drug, which is predominantly excreted renally, is often prescribed together with the beta-lactamase inhibitor tazobactam (TAZ) as a fixed combination. After intermittent administration, PIP concentrations varied substantially among critically ill patients [6–10]. However, most studies have evaluated only limited numbers of patients or defined patient subgroups, resulting in inconclusive information regarding just how substantial the inter-individual variation of PIP concentrations is in a typical heterogeneous ICU patient group. Recent studies have been performed with high patient numbers [11–13], but limited numbers of PIP concentrations were determined per patient. Indeed, there is only one report concerning PIP concentrations over an entire 7-day antibiotic course in critically ill patients [6]; the 11 patients included in that study exhibited coefficient of variations (CV) of 20–60 % for within-patient variability (for trough levels). Because this variability was evaluated only in patients with normal renal function, it remains unclear if this result reflects the typical intra-individual variability within ICU patients.

It has been shown that the high variability of piperacillin levels observed in ICU patients often leads to potentially subtherapeutic levels. This is mostly dependent on renal function; therefore – according to expert information and guidelines – different dosage schemes are recommended depending on creatinine clearance. Udy et al. recently evaluated PIP levels in dependence of creatinine clearance in critically ill patients with septic shock/severe sepsis receiving 4.5 g PIP-TAZ four times daily by intermittent short-term infusions. In patients grouped by creatinine clearance quartiles, most patients showed potentially insufficient PIP trough levels when creatinine clearance was 115–170 mL/min or > 170 mL/min [14]. Administration of 4.5 g PIP-TAZ three times daily (TID) was also shown frequently to result in insufficient levels in critically ill patients with moderately impaired renal function [15]; however, this was evaluated in the early phase of treatment, and it is not clear if this result is transferable to later therapy time points. Indeed, many physicians still usually prescribe only 4.5 g PIP-TAZ TID for critically ill patients, especially for patients with mildly or moderately impaired renal function, and 4.5 g PIP-TAZ twice daily (BID) in cases of severely

impaired renal function. Some authors assumed that the usual reduction of the piperacillin dosage especially for patients with severely impaired renal function might be critical in case of serious illness. Indeed, according to the German guideline “Epidemiology, diagnosis and treatment of adult patients with nosocomial pneumonia,” critically ill patients, in particular with a reduced dose because of impaired renal function, might be underdosed [16]. Therefore, it is recommended here that the first dose should not be adapted in patients with septic shock/severe sepsis with severely impaired renal function. However, studies describing PIP levels with such a dosage regimen (4.5 g PIP-TAZ BID) in critically ill patients are still lacking.

Therefore, we designed a prospective observational study to analyze the variability of PIP in a patient group of critically ill patients. The aim was to determine if PIP was in its therapeutic range in a typically heterogeneous ICU patient group and also to describe target attainment dependent on daily dose, creatinine clearance, and renal replacement therapy (RRT).

Methods

Patients

Sixty consecutive patients who met the inclusion criteria and who were hospitalized from September 2013 to September 2014 in one of three ICUs within the Department of Anaesthesiology, University Hospital of Munich, were included. The inclusion criteria consisted of the presentation of severe infection (confirmed or clinically assumed) and the therapeutic intravenous administration of PIP-TAZ via short-duration infusions. The exclusion criteria were age < 18 years, a planned hospitalization time of < 4 days and the administration of PIP-TAZ more than 48 hours before the study began. Written informed consent for study inclusion was obtained from all patients or their legal representatives.

Study design

The study protocol (NCT01793012) for this prospective observational study was approved by the ethics committee of the Ludwig Maximilians University and was performed in accordance with the ethical standards set forth by the 1964 Declaration of Helsinki and its later amendments. Patients received 4.5 g of PIP-TAZ BID or TID depending on renal function according to clinical guidelines. The beginning of the study (day 1) was defined as the time point at which the first blood sample was taken from each patient to determine PIP concentrations. Serum samples for antibiotic determination were collected at multiple time points immediately before (trough level), during, and after all PIP-TAZ administrations on day 1 (sampling after the start of PIP-TAZ administrations at 0.25, 0.5, 1.5, 4, 7.25 or 8, and

12 hours, if appropriate). On days 2, 3, and 4, samples were collected during only one of the PIP-TAZ intervals (sampling at the same time points). The exact time of blood sampling was recorded by the medical staff. Serum samples for determination of PIP levels were immediately (<15 minutes) sent by pneumatic delivery system to the Institute of Laboratory Medicine. There, samples were immediately centrifuged, aliquoted, stored within 1 hour after sampling at -20 °C, and finally, within 24 hours after sampling, at -80 °C.

Laboratory and clinical parameters

Total PIP concentrations were determined using a two-dimensional ultra-high-performance liquid chromatography/tandem mass spectrometry (UHPLC-MS/MS) method as previously described [17]. Five-fold deuterated piperacillin was used as the internal standard. Validation revealed good analytical performance with an inaccuracy $\leq 5\%$ and imprecision $\leq 5\%$ (CV) for all quality control samples. For renal function evaluation, 24-hour urine was collected and creatinine clearance (CL_{crea}) was calculated using the formula:

$$CL_{crea} = (C_{urine} * V_{urine}) : (C_{serum} * time),$$

where C_{urine} is the creatinine concentration in urine, V_{urine} is the urine volume, and C_{serum} is the serum creatinine concentration. Diagnosis, laboratory and clinical parameters/scores were recorded daily in the ICUs.

Strains

Pathogens isolated from the patients between 6 days before and 6 days after the study began were recorded. Susceptibility to PIP-TAZ for bacteria was determined in accordance with the breakpoints as described by the European Committee on Antimicrobial Susceptibility Testing [18].

Correlation of outcome parameters with PIP concentrations

Outcome parameters (mortality within 28 days and ICU-free days on day 28) and C-reactive protein (CRP) levels were evaluated in all patients and in a subgroup of patients defined as outcome group. In this group, only patients with bacterial isolates that met all the following criteria were included: (1) the isolates were clinically assumed to be causative strains for the patients' infection, (2) all assumed causative strains were bacteria and were sensitive to PIP-TAZ, (3) but not to other antibiotic substances given to the patient. PIP trough levels of day 1 were correlated with alive ICU-free days on day 28 and with 28-day mortality. For CRP, we correlated PIP trough levels with CRP concentrations and with changes of CRP (CRP quotients). Finally, we correlated PIP

trough levels of day 1 with possible neurotoxic effects within the study period (patients with delirium, somnolence, or seizures within the study period) in all patients.

Assessment of target concentration ranges

The thresholds for the potential therapeutic efficacy of total PIP were defined as >22.5 mg/L for trough levels (target range 1) and/or a percentage of time >90 mg/L (%T >90 mg/L) of $\geq 50\%$ (target range 2). The 22.5 mg/L trough level corresponds to a percentage of time above the minimal inhibitory concentration (%T $>MIC$) of 100% [13, 14] using a MIC value of 16 mg/L [6, 14, 18] and taking into account an average protein-binding fraction of 30% [12, 19–22]. Analogously, %T >90 mg/L of $\geq 50\%$ corresponds to a %T $>4 \times MIC$ of $\geq 50\%$ in accordance with the literature [19, 23].

Pharmacokinetic analysis

PIP trough levels, as measured using UHPLC-MS/MS, were evaluated. For the determination of the percentage of time the PIP concentrations remained above 90 mg/L or 22.5 mg/L, we connected the different determined PIP concentration points between two consecutive PIP-TAZ administrations and determined the time point at which the PIP concentration fell below 90 mg/L or 22.5 mg/L, respectively. The time between the beginning of the previous PIP-TAZ administration and this time point was set in relation to the entire time between the two respective PIP-TAZ administrations.

Statistics

The boxplots represent the medians and interquartile ranges, and the ends of the whiskers represent the 5th and 95th percentiles. The intra-patient variability CV was calculated by dividing the individual standard deviation by the mean of a given patient's trough levels. The Spearman correlation coefficient was used to describe the correlations between continuous parameters. The Wilcoxon-Mann-Whitney test was used to test significance between different groups.

Results

The beginning of the sampling was 6.9–45.6 hours (median, 18.7 hours) after the first PIP-TAZ administration. Over the 4-day study, multiple blood samples (median, 29; interquartile range (IQR) 20–33) were taken from each patient. The 60 patients exhibited a high heterogeneity in clinical and laboratory characteristics (Table 1). The most frequent causes of infection were pneumonia ($n = 36$) and peritonitis ($n = 7$). Twelve patients suffered from acute respiratory distress syndrome. Seven patients were post-lung, and eight patients were post-liver transplant patients. Three patients were treated with extracorporeal lung assist, and ten patients were treated with

renal replacement therapy (RRT) (day 1). In total, 33 gram-positive bacterial strains, 19 gram-negative bacterial strains, 23 fungal and six viral strains were detected in the patients.

A total of 1627 PIP concentrations were included for evaluation. Additional file 1 shows the concentration time curves of serum PIP concentrations in all patients. A high inter-individual variability for PIP was observed. This result was not restricted to the beginning of the study period (range of trough levels on day 1: 928-fold, 0.18–167 mg/L) but was observed over 4 days (range of trough levels 123-fold to > 1785-fold at each day 2, 3, and 4) (Fig. 1a). The PIP concentration variability was similarly substantial in patients who received PIP-TAZ TID (range of trough levels 99-fold to > 1549-fold on the different study days) (Fig. 1b), a patient group characterized by higher creatinine clearance (Table 1). In contrast, less variability was observed in the PIP concentrations of patients who received PIP-TAZ only BID (range of trough levels 6.2-fold to 13.8-fold on the different study days) (Fig. 1c), a patient group characterized by the presence of strongly impaired renal function.

Intra-patient variability was much lower than inter-patient variability. Over 4 days, only four patients exhibited maximum trough levels greater than 10-fold higher than the minimum trough levels. Most of the 60 patients exhibited values either always (n = 22) or partly below (n = 14) the target threshold. CVs for within-patient PIP variability ranged from 6.4 to 129 % (median, 30 %; IQR, 23–44 %). The PIP trough level of most patients did not change in a consistent pattern over the 4 days of the study; only in patients 15, 17, 25, 45, and 51 we did observe a continuous decrease, and in patient 59 a continuous increase of PIP trough levels over time (Additional file 1).

Approximately 50 % of all study patients exhibited PIP levels below target range 1 (trough levels < 22.5 mg/L) (Table 2). Over 4 days, adequate trough levels of PIP were observed in almost all patients from the patient group with the lowest quartile of creatinine clearance (100 % on day 1). In contrast, adequate PIP trough levels were not observed in the patient group with the highest quartile of creatinine clearance over the course of 4 days. Similarly, adequate PIP trough levels were reached by almost all patients who received PIP-TAZ BID because of

impaired renal function (100 % on day 1; IQR of creatinine clearance: 6–19 mL/min), whereas this target was only reached by the minority of patients receiving PIP-TAZ TID (38 % for PIP on day 1; IQR of creatinine clearance: 40–130 mL/min). Indeed, in patients who received PIP-TAZ TID (patients on RRT excluded), no patient with a creatinine clearance > 65 mL/min, and only 55 % of the patients with a creatinine clearance ranging from 30 to 65 mL/min, reached this target (Additional file 2). In contrast, patients with equal antibiotic dosages

and a creatinine clearance < 30 mL/min always had piperacillin levels within the therapeutic range. The dependency of trough levels on creatinine clearance was proven ($r = -0.837$) ($p < 0.001$).

Similar observations with respect to target attainment were made for the specific patient subgroups when using target range 2 (≥ 50 %T > 90 mg/L); however, fewer patients of the patient subgroups were in the therapeutic range (e.g., approximately 40 % of total patients over 4 days) (Table 2, Additional file 3). Whereas the difference between target attainment of target range 1 and 2 was low for patients who received PIP-TAZ TID (38 % versus 33 % on day 1, respectively), a high difference was observed for patients who received PIP-TAZ BID (100 % versus 64 %) (Table 2).

Over 4 days, adequate trough levels of PIP were observed in most patients with RRT (80 % on day 1) (Table 2). Indeed, presence of RRT [different daily dosages (BID or TID) and different RRT methods used, see Additional file 4] was associated with significant higher percentages of T > 22.5 mg/L (Fig. 2) ($p < 0.001$). Target attainment of the different subgroups in dependence of dosing, creatinine clearance, and use of RRT are shown in Additional file 5.

PIP trough levels had no significant effects on both mortality and ICU-free days on day 28 in all patients. Within 28 days, six patients died, 40 patients survived and 14 patients were discharged from hospital. The median of ICU-free days at day 28 was 14 (IQR 0–23). We further analyzed the outcome group as defined in Methods: also here, no significant effects of PIP trough levels on both mortality and ICU-free days on day 28 were observed. Finally, we evaluated if PIP trough levels might have at least an effect on the course of inflammation parameters within 4 study days. In the outcome group, we observed a significant negative correlation between CRP concentrations on day 4 versus PIP trough levels over time (Table 3). A similar trend for day 3 and 4 was observed when quotients of CRP concentrations were correlated with PIP trough levels over time.

Finally, there was no difference in the presence of PIP trough concentrations on day 1 and possible neurotoxic effects over the study period.

Discussion

In our ICU patient group, we observed a very high variability of PIP levels leading to a high percentage of patients with potentially subtherapeutic PIP concentrations. Target attainment was tightly associated with creatinine clearance. Although the strong association between creatinine clearance and piperacillin levels has already been described in several studies of critically ill patients, this work is novel in contemporary literature, given the number of blood-sampling time points, the

variability of piperacillin levels observed over several days, the difference of target attainment dependent on both creatinine clearance and commonly used dosage schemes, and the increasing negative association of PIP trough levels with CRP levels during therapy. Our data highlights the concern that patients with mild or moderate renal function impairment are also likely to have subtherapeutic levels over several days with the

conventional intermittent dosage scheme of 4.5 g PIP-TAZ TID. This might lead to treatment failure or the selection of drug-resistant strains. In contrast, there might be less risk of subtherapeutic trough levels and treatment failure in ICU patients with severely impaired renal function and use of RRT, even when the dosage is reduced to 4.5 g PIP-TAZ BID.

Previous studies have also described a high dependency of PIP concentrations on creatinine clearance [14, 15, 24–29]. However, only Conil et al. described the effect on target attainment when using this conventional dosing in patients with slightly to moderately impaired renal function [15]. They observed a correlation coefficient of -0.61 , whereas we observed an even higher correlation ($r = -0.837$) for patients receiving 4.5 g PIP-TAZ TID. Because Conil et al. determined PIP concentrations at precisely the time point of 24 hours after starting antibiotic treatment, it remained unclear if the observed high percentage of subtherapeutic levels in their study might also have resulted from insufficient loading and how often the target range would be attained at a later time points. The high correlation coefficient we found may open the possibility to develop a pharmacokinetic model, which might help to find adequate dosing especially in dependence of creatinine clearance values. We showed that the percentage of insufficient levels remained high and more or less stable in patients over the course of several days. Moreover, all patients with a creatinine clearance > 65 mL/min and approximately half of patients with a creatinine clearance between 30 and 65 mL/min had insufficient levels, even with the lower therapeutic range (therapeutic range 1). This shows that this dosage may be insufficient over several days also for patients who have slightly or moderately impaired renal

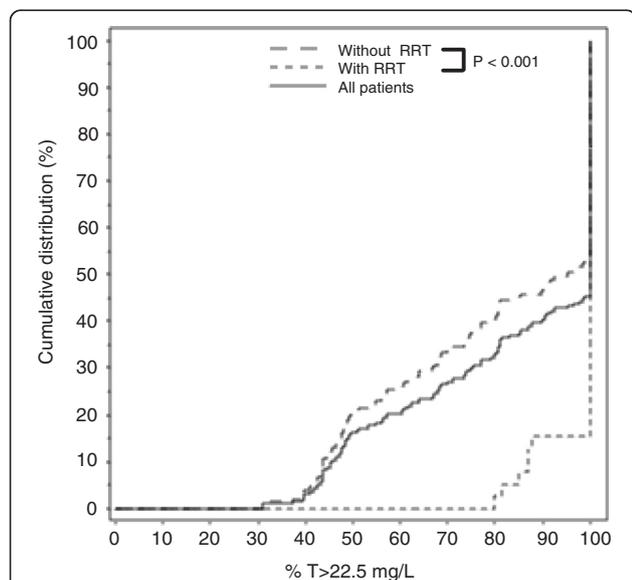

Fig. 2 Effects of renal replacement therapy on percentage of time > 22.5 mg/L of piperacillin. Percentage of time of piperacillin (PIP) > 22.5 mg/L for values of all patients, for values of patients with renal replacement therapy (RRT), and for values of patients without RRT are shown. From each patient, one value was evaluated per day, and values of the 4 days of all patients were evaluated simultaneously

^aIn this group, only patients with bacterial isolates that met all the following criteria were included: (1) the isolates were clinically assumed to be causative strains for the patients' infection, (2) all assumed causative strains were bacteria and were sensitive to PIP-TAZ, (3) but not to other antibiotic substances given to the patient

^bOnly one piperacillin trough level used per day

function. To reach the target range 1, it might be reasonable in cases of slightly to moderately impaired renal function to prescribe the maximum dosage of 4.5 g PIP-TAZ four times daily, as recommended by the prescription drug information. However, occurrence of neurotoxicity, although not clearly observed in our study, should be carefully monitored. Moreover, to the best of our knowledge, we showed for the first time that an adjusted PIP dosage of 4.5 g PIP-TAZ BID for patients with strongly impaired renal function leads to therapeutic levels in critically ill patients much more often (Table 2). Interestingly, for these patients, this was much more dependent on the defined therapeutic range (1 versus 2). Whereas most patients reached therapeutic range 1 (82–100 % at different study days), only 50–64 % reached therapeutic range 2 (Table 2). This might be due to the longer time intervals between consecutive doses in this case, which makes it more difficult to reach a high concentration over a long time interval. There is still a controversial debate about the right target range

for critically ill patients [13]. However, the high percentage of patients with severely impaired renal function and reduced dosage reaching at least the target range 1 shows that the problem of underdosing in this patient group is much lower than in patients with slightly or moderately impaired renal function and not an adjusted dosage. This is still important, because many ICU physicians still prescribe PIP-TAZ 4.5 g TID – at least for patients with slightly to severely impaired renal function. Indeed, these dosages are still recommended by the Food and Drug Administration and in expert information.

We also evaluated the influence of RRT on PIP concentrations. This is important as the use of RRT may further alter antibiotic pharmacokinetics [30]. We observed significant higher percentages of $T > 22.5$ mg/L for the patients with RRT. Because of the different RRT methods and the different daily dosages, we only had limited numbers of the specific subgroups. Therefore, we could not evaluate the influence of the different RRT modalities on PIP concentrations.

Considering all patients, we observed a high variability and a high quantity of subtherapeutic levels for PIP, as in other studies [6, 9, 19, 21, 31, 32]. In contrast with the literature, we observed an even higher inter-individual variability for PIP trough levels [6, 9, 19, 21, 33] and a higher percentage of patients with PIP levels below $fT > MIC$ [6, 9, 14] and below the higher target range of $50\% fT > 4 \times MIC$ [9, 19, 23]. Sime et al., however, observed a higher percentage of patients with trough levels below the target range [21], which might be due to the average higher creatinine clearance (all patients > 50 mL/min) of their study patients. The high inter-individual variability we observed in our study with trough levels varying > 100 -fold was restricted to patients who received PIP-TAZ TID (Fig. 1), which might be at least in part due to the higher range of creatinine clearance in this group. We also found partly higher inpatient variability than in the literature: over 4 days, we observed CVs for PIP ranging from 6 to 129 %, whereas Carlier et al. reported CVs of 20–60 % over an entire antibiotic course [6]. The reason for the higher variability observed in our study might be the higher heterogeneity of patient characteristics. As this is typical for ICU patients, our data might support the concept of therapeutic drug monitoring (TDM).

Thresholds of both target ranges for unbound PIP were defined as in other studies [6, 9, 14, 19, 21, 23]. A traditional target for this antibiotic is $40\text{--}50\% fT > MIC$ [34]. However, a higher target range might be more appropriate for ICU patients [31] because of the critical illnesses of these patients. Therefore, we chose $100\% fT > MIC$ in accordance with most other studies [6, 9, 14, 21]. Indeed, different studies demonstrated that for beta-lactam antibiotics, maximum killing is often only achieved when the $T > MIC$ approaches 90–100 % of the dosing interval [35]. The higher target range ($50\% fT > 4 \times MIC$) was chosen in accordance with other studies [19, 23], because antibacterial killing of beta-lactam antibiotics might be maximal when the antibiotic is $4\text{--}5 \times MIC$ [36]. A long time-interval above such a higher threshold might also be positive to reduce the development of antibiotic resistance [3]. However, it should be noted that even higher target ranges (i.e., $100\% fT > 4 \times MIC$) might be useful to maximize the antimicrobial effect and minimize the development of resistance in these patients [3, 19]. Target attainment might also vary in dependence of microorganism idiosyncrasies such as inoculum [37]. Future prospective interventional studies are required to investigate which target ranges are associated with the best outcome for patients, thereby also minimizing the risk for the development of antibiotic resistance in the intensive care unit.

Outcome parameters such as alive ICU-free days, 28-day mortality, or occurrence of adverse reactions did

not correlate with PIP levels in all patients. However, because of the patient number and the heterogeneous patient group used, short-term effects of antimicrobial therapy on alive ICU-free days and 28-day mortality might not be visible in this group. We therefore also correlated CRP concentrations in both all patients and in the outcome group. In the outcome group, we found a negative correlation of CRP concentrations at day 4 with PIP trough levels ($p < 0.05$). Furthermore, a trend to a faster CRP decrease in cases of high PIP trough levels was also observed at day 3 and 4 (both $p < 0.1$, Table 3). We thought that it might be important to define an outcome group, because we wanted to evaluate only relevant patients, where PIP-TAZ was the only antimicrobial therapy effective against the causative pathogens. As it has not yet been shown in the literature for piperacillin that target attainment of our targets correlates with a positive clinical or microbiological outcome, the targets used in our study have to be regarded only as a limited approach. However, our data indicate that at least higher concentrations of PIP might be associated with a faster decrease of the inflammation parameter CRP.

This study has some limitations. (1) The data were drawn from a single center. Indeed, PIP pharmacokinetics might be different among patients from different ICUs. To minimize this limitation, we included a relatively high number of patients and allowed a high heterogeneity of patient characteristics to best represent the full spectrum of different patients in ICUs. (2) We did not measure the unbound fraction of PIP from stored serum samples, e.g., via centrifugal filter devices. Indeed, it remains unclear if PIP might be bound to the filter in a relevant percentage and if freeze-thaw cycles might alter the protein-binding fraction. However, we considered a fixed protein-binding fraction of 30 % in the definitions of the target ranges. This may be a problem in individual patients, because unbound PIP fractions may differ substantially in individual critically ill patients, especially in those with altered protein levels. (3) Higher thresholds of the target ranges were not defined, as no robust data are existent. However, definition of such thresholds may also be important because it has been shown that the neurotoxicity of some beta-lactam antibiotics may be probably underestimated in critically ill patients [38]. (4) Only two different dosing schemes were evaluated. Some authors have used higher doses for critically ill patients [6, 14]; however, the dosage schemes used in our study are still recommended by the Food and Drug Administration and in expert information. Prolonged or continuous infusions have also been recommended [34]. Indeed, it has been shown by Abdul-Aziz et al. that prolonged infusion of piperacillin can be associated with a better outcome [39] but no difference

in the clinical outcome was observed in other studies [40, 41]. Moreover, some authors also write that a prolonged or continuous infusion eventually promotes that resistant mutants are selectively amplified, and that these mutants therefore might become the dominant bacterial population [2] (5) Finally, we did not use pharmacokinetic modeling to describe %T > 90 mg/L or trough levels. Such models are especially relevant if only few samples per patient are available or if concentrations around the peak value have to be described. We did not perform pharmacokinetic modeling because we collected multiple blood samples between consecutive antibiotic administrations (Additional file 1), and we only described the %T > 90 mg/L and the trough levels, which were always on the descending concentration time curves. Indeed, imprecise individual predictions might occasionally occur with pharmacokinetic modeling if the individual estimated parameter values vary substantially from those of the typical population, which might be a problem in a highly heterogeneous patient group as in our study [42].

Conclusions

Our data emphasize that the conventional dosing of 4.5 g PIP-TAZ TID may often lead to insufficient blood levels in critically ill patients, and also in patients with slightly or moderately impaired renal function. In contrast, underdosing might be less common in patients with severely impaired renal function or in patients with RRT, also in cases of 4.5 g PIP-TAZ BID.

Key messages

- A high inter- and intra-individual variability of piperacillin levels was observed leading to a continuously high percentage of potentially subtherapeutic levels over several days during the acute phase of severe infections.
- Piperacillin trough levels were tightly associated with creatinine clearance.
- Only the minority of patients who received PIP-TAZ 4.5 g TID had trough levels for the calculated unbound fraction of piperacillin > 16 mg/L (target range 1), whereas most patients who received PIP-TAZ 4.5 g only BID because of severely impaired renal function attained this target range.
- Use of renal replacement therapy led to significant higher percentages of T > 16 mg/L for the calculated unbound fraction of piperacillin.
- In patients with causative strains only sensitive to PIP-TAZ of all antibiotics given to the patient, piperacillin levels negatively correlated with CRP concentrations of day 4 ($p < 0.05$).

Additional files

Additional file 1: Piperacillin serum concentrations of all patients. A figure showing the piperacillin serum concentrations of all patients over the course of 4 days. Piperacillin concentrations from two to three administrations on day 1 and from one administration on day 2–4 are presented. Single points always represent trough levels; ¹patient number of each subfigure. (PPTX 838 kb)

Additional file 2: Piperacillin trough levels in relation to creatinine clearance for patients who received 4.5 g piperacillin-tazobactam three times daily. A figure showing piperacillin levels in relation to creatinine clearance. Only patients without use of renal replacement therapy are shown. The second trough level, if available, is presented per day and per patient. (PPTX 51 kb)

Additional file 3: Distribution of percentage of time with piperacillin values > 90 mg/L. A figure showing the percentage of target attainment of target 2 ($\geq 50\%$ > 90 mg/L) in different patient subgroups. Percentage of time of piperacillin > 90 mg/L (a) for all patients, (b) for patients receiving piperacillin-tazobactam three times daily and (c) for patients receiving piperacillin-tazobactam two times daily because of impaired renal function are shown. Boxplots represent medians and interquartile ranges, the ends of the whiskers represent the 5th and 95th percentiles. (PPTX 1153 kb)

Additional file 4: Renal replacement therapy and dosage of piperacillin-tazobactam A table showing the type of renal replacement therapy and the daily dosage for each patient. CVHD, continuous veno-venous hemodialysis; CWH, continuous veno-venous hemofiltration; CWHDF, continuous veno-venous hemodiafiltration; IHD, intermittent hemodialysis; TID, piperacillin-tazobactam 4.5 g three times daily; BID, piperacillin-tazobactam 4.5 g twice daily. (DOCX 15 kb)

Additional file 5: Target attainment in dependence of subgroups. A table showing the target attainment of values in dependence of actual piperacillin-tazobactam dosage, creatinine clearance, and use of renal replacement therapy. From each patient, one value was evaluated per day in the corresponding subgroup (each day grouped in dependence of the actual creatinine clearance, dosage of piperacillin, or actual use of renal replacement therapy). All values of all days of the different subgroups were evaluated simultaneously. TID, piperacillin-tazobactam 4.5 g three times daily; BID, piperacillin-tazobactam 4.5 g twice daily; CrCl creatinine clearance; RRT, renal replacement therapy. ¹The second trough levels, if available, was evaluated per day and per patient; ²values from the first to the second piperacillin-tazobactam administration were used, if available, per day and per patient; ³this subgroup included values of the two patients with the highest body mass index, i.e., 37 and 41 kg/m². (DOCX 15 kb)

Abbreviations

%T > 90 mg/L: percentage of time >90 mg/L; %T > MIC: time above the minimal inhibitory concentration; BID: twice daily; CRP: C-reactive protein; CV: coefficient of variations; FT > MIC: time above the minimal inhibitory concentration for the unbound antibiotic; ICU: intensive care unit; IQR: interquartile range; PIP: piperacillin; RRT: renal replacement therapy; TAZ: tazobactam; TDM: therapeutic drug monitoring; TID: three times daily; UHPLC-MS/MS: ultra-high-performance liquid chromatography/tandem mass spectrometry.

Competing interests

The authors declare that they have no competing interests.

Authors' contributions

MZ and JZ designed the study and wrote the manuscript. BM measured the antibiotic concentrations by LC-MS/MS; GD, CS, and MHZ were responsible for acquisition of data; DN performed the statistical analyses. JJ, LF and MV made substantial contributions to the conception and design of the study including interpretation of results. All authors critically revised the manuscript for important intellectual content and approved the final manuscript. All authors meet key authorship requirements and agree to be accountable for all aspects of the work in ensuring that questions related to the accuracy or integrity of any part of the work are appropriately investigated and resolved.

Acknowledgements

This study was supported by a Mériex Research Grant (Institut Mériex, Lyon, France). The design, collection, analysis and interpretation of data, as well as the writing and publication of the manuscript were done by the authors without participation or influence from the funding source.
